informatique

# Outline

---

- Organization of the global Internet
  - ● Example of domains
  - Intradomain routing
- BGP basics
- BGP in large networks
- Interdomain traffic engineering with BGP
- BGP-based Virtual Private Networks

# How to route IP packets in the global Internet ?

A map of the global Internet in 2000 ...

# Organization of the Internet

---

- Internet is composed of more than 10.000 **autonomous routing domains**
- A domain is a set of routers, links, hosts and local area networks under the same administrative control
  - ◆ A domain can be very large...
    - ◆ AS568: SUMNET-AS DISO-UNRRA contains 73154560 IP addresses
  - ◆ A domain can be very small...
    - ◆ AS2111: IST-ATRIUM TE Experiment a single PC running Linux...
- Domains are interconnected in various ways
  - ◆ The interconnection of all domains should in theory allow packets to be sent anywhere
  - ◆ Usually a packet will need to cross a few ASes to reach its destination

# Types of domains

- Transit domain

- A **transit domain allows** external domains to use its own infrastructure to send packets to other domains

- Examples

- UUNet, OpenTransit, GEANT, Internet2, RENATER, EQUANT, BT, Telia, Level3,...

# Types of domains (2)

- Stub domain

- A stub domain does not allow external domains to use its infrastructure to send packets to other domains
  - ◆ A stub is connected to at least one transit domain
    - ◆ Single-homed stub : connected to one transit domain
    - ◆ Dual-homed stub : connected to two transit domains

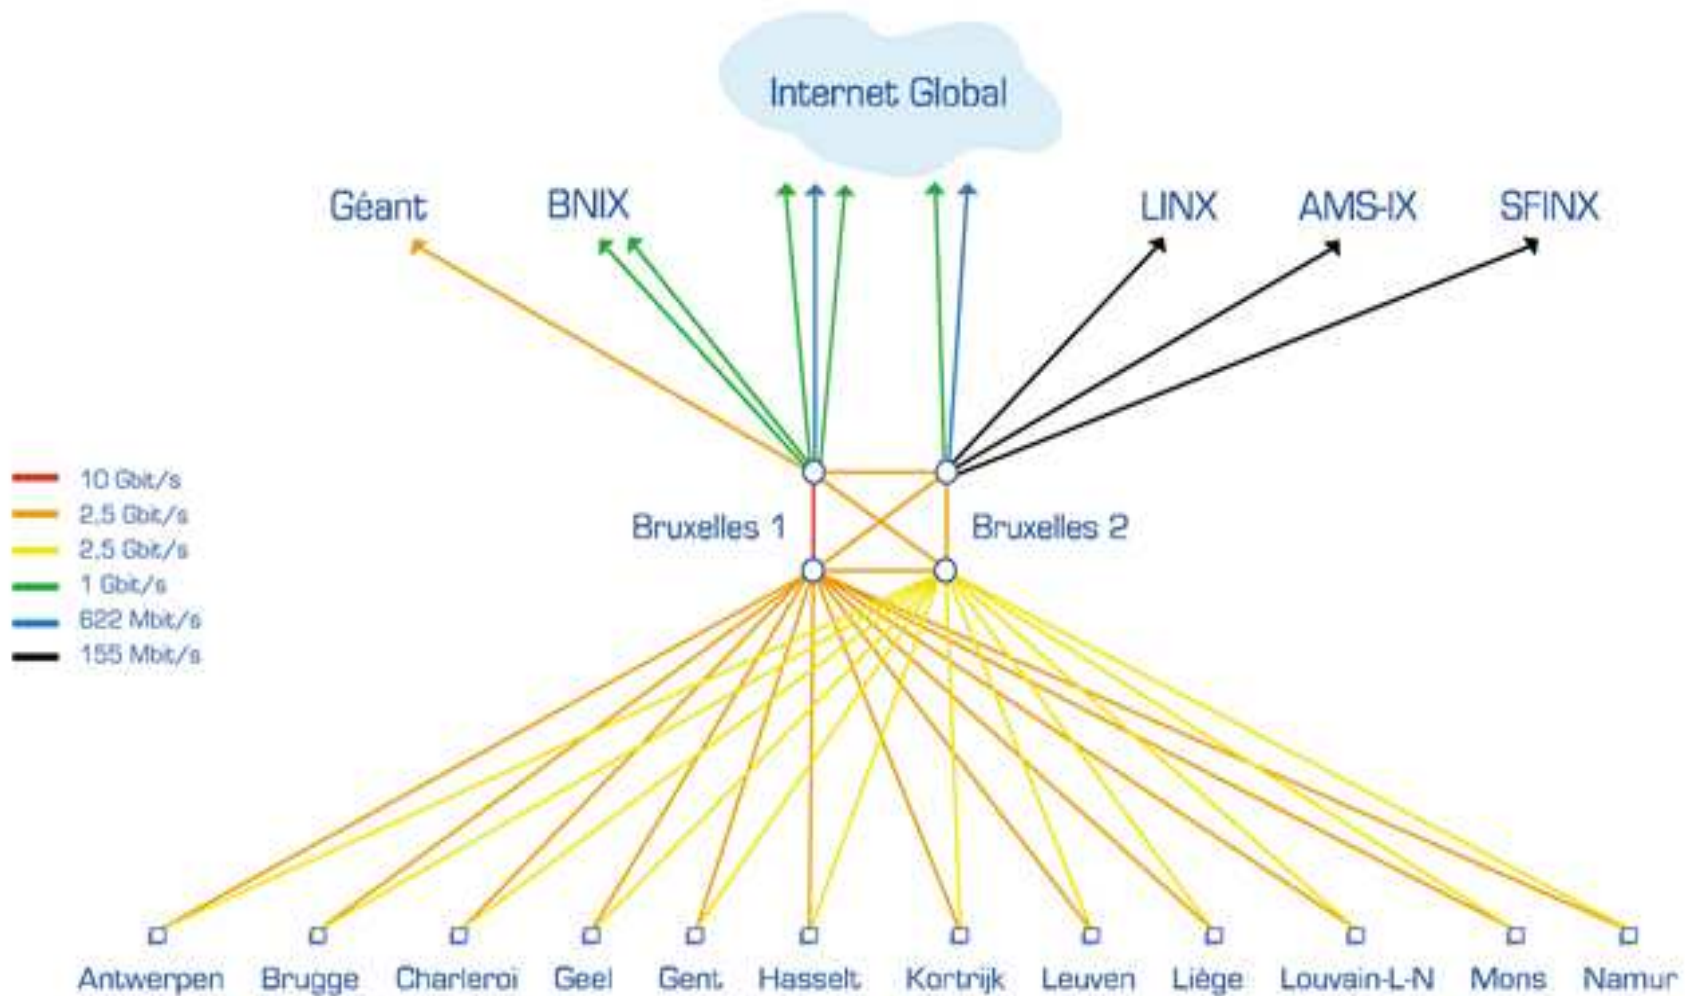

- Content-rich stub domain

- ◆ Large web servers : Yahoo, Google, MSN, TF1, BBC,...

- Access-rich stub domain

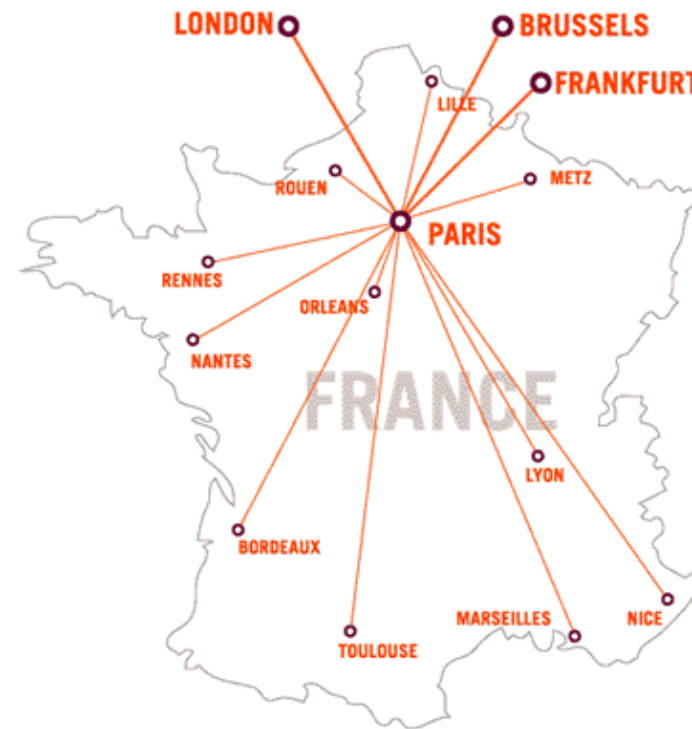

- ◆ ISPs providing Internet access via CATV, ADSL, ...

# A Stub domain : Belnet

# A transit domain : Easynet

---

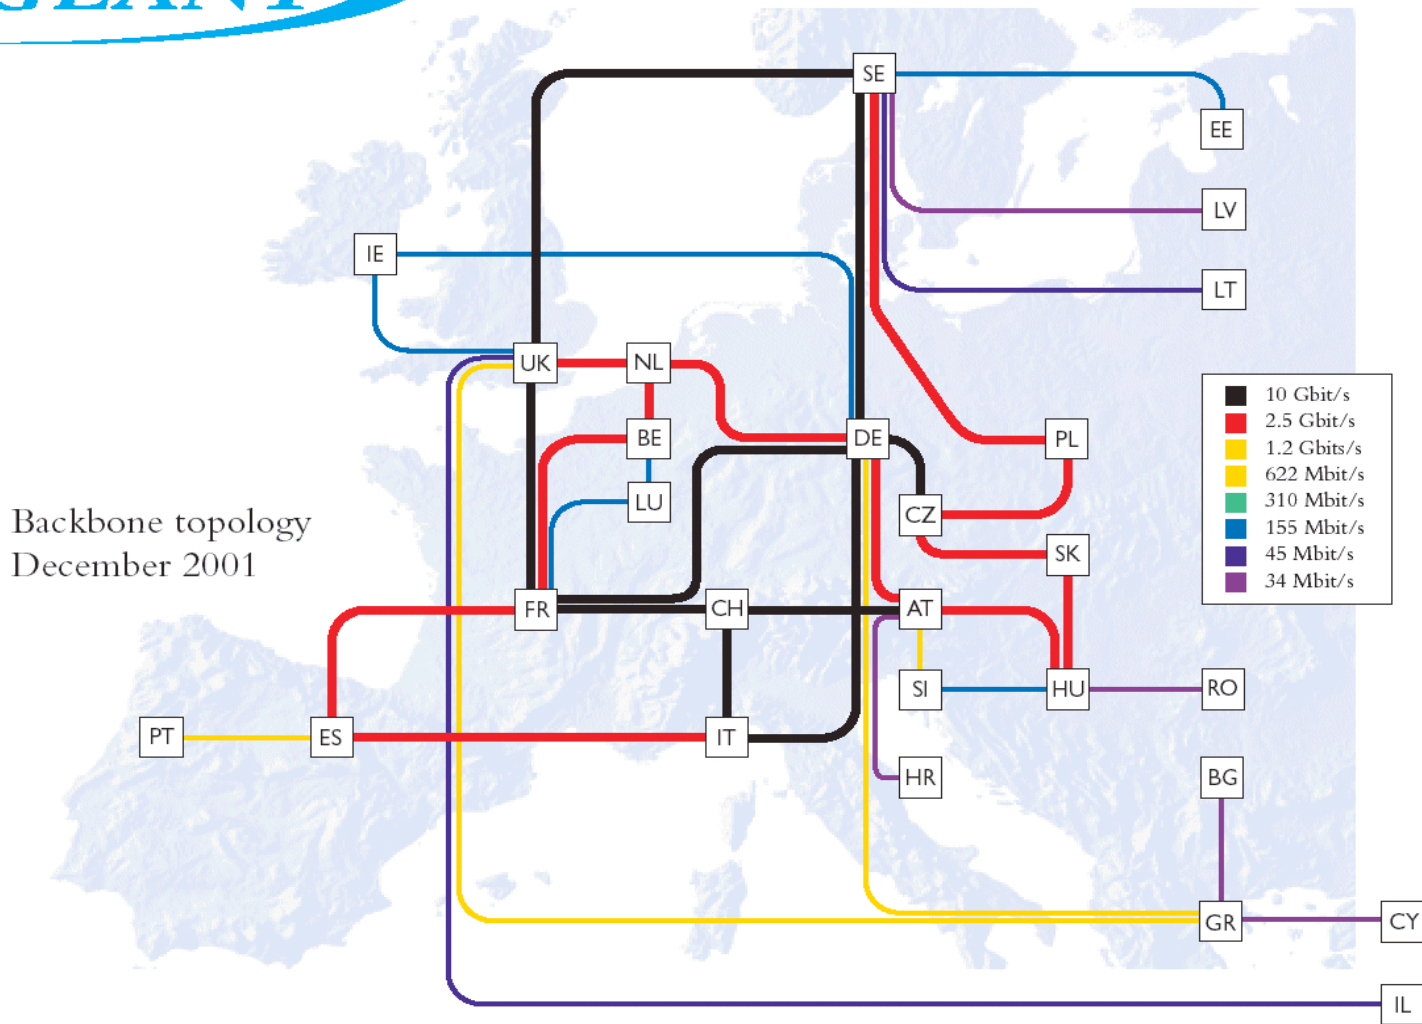

# A transit domain : GEANT

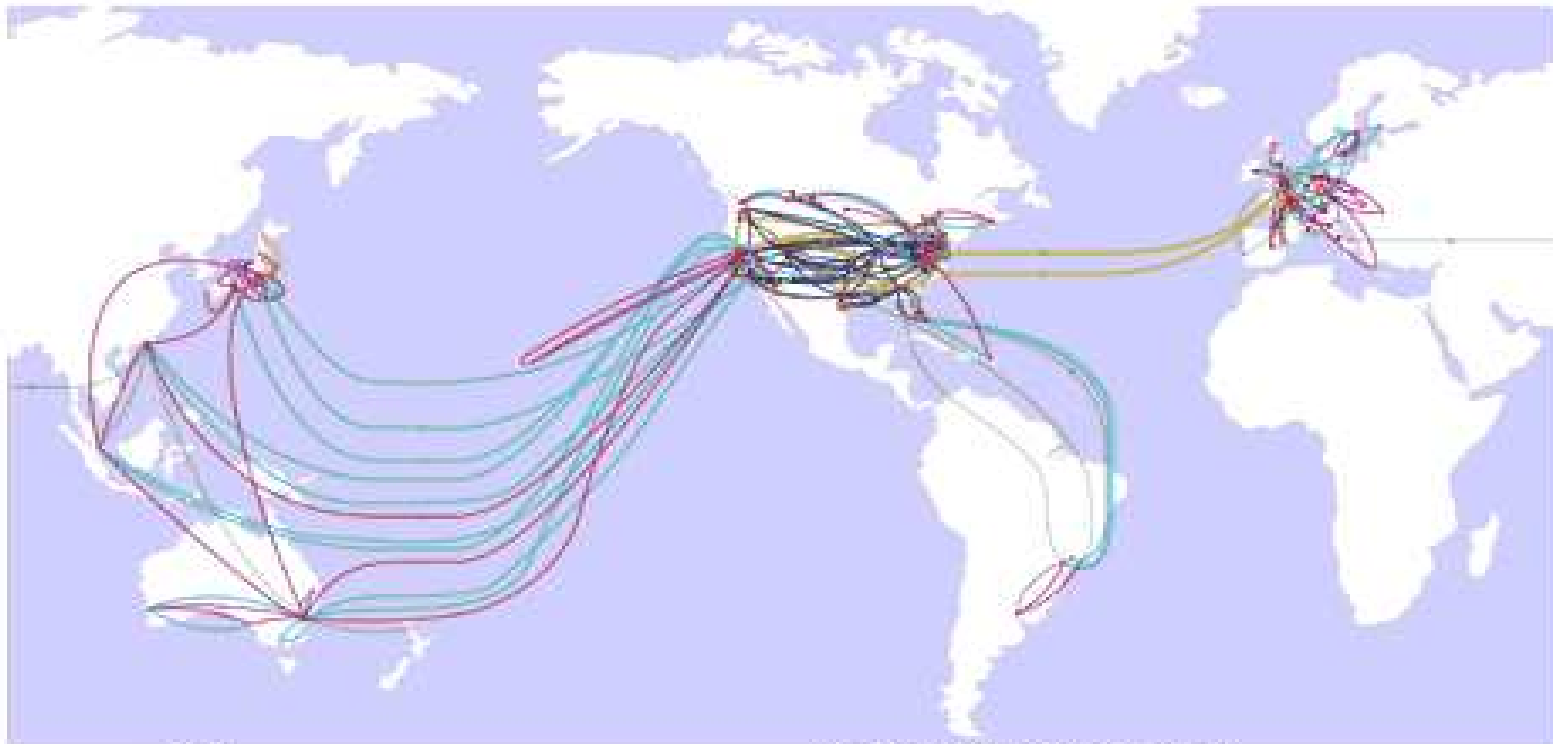

The Gigabit Research Network

# A transit domain : BT/IGnite

# A large transit domain : UUNet

- |                               |                          |
|-------------------------------|--------------------------|
| — 64 Kbps                     | — OC12c/STM4 (622 Mbps)  |
| — T1/E1 (1.5 Mbps/2 Mbps)     | — OC48c/STM16 (2.5 Gbps) |
| — E3/T3/DS3 (35 Mbps/45 Mbps) | — OC192c/STM64 (10 Gbps) |
| — T2 (6 Mbps)                 | • Single Hub City        |
| — OC3c/STM1 (155 Mbps)        | ■ Multiple Hubs City     |
|                               | ■ Data Center Hub        |

# Outline

---

- Organization of the global Internet

- Example of domains

- ● Intradomain routing

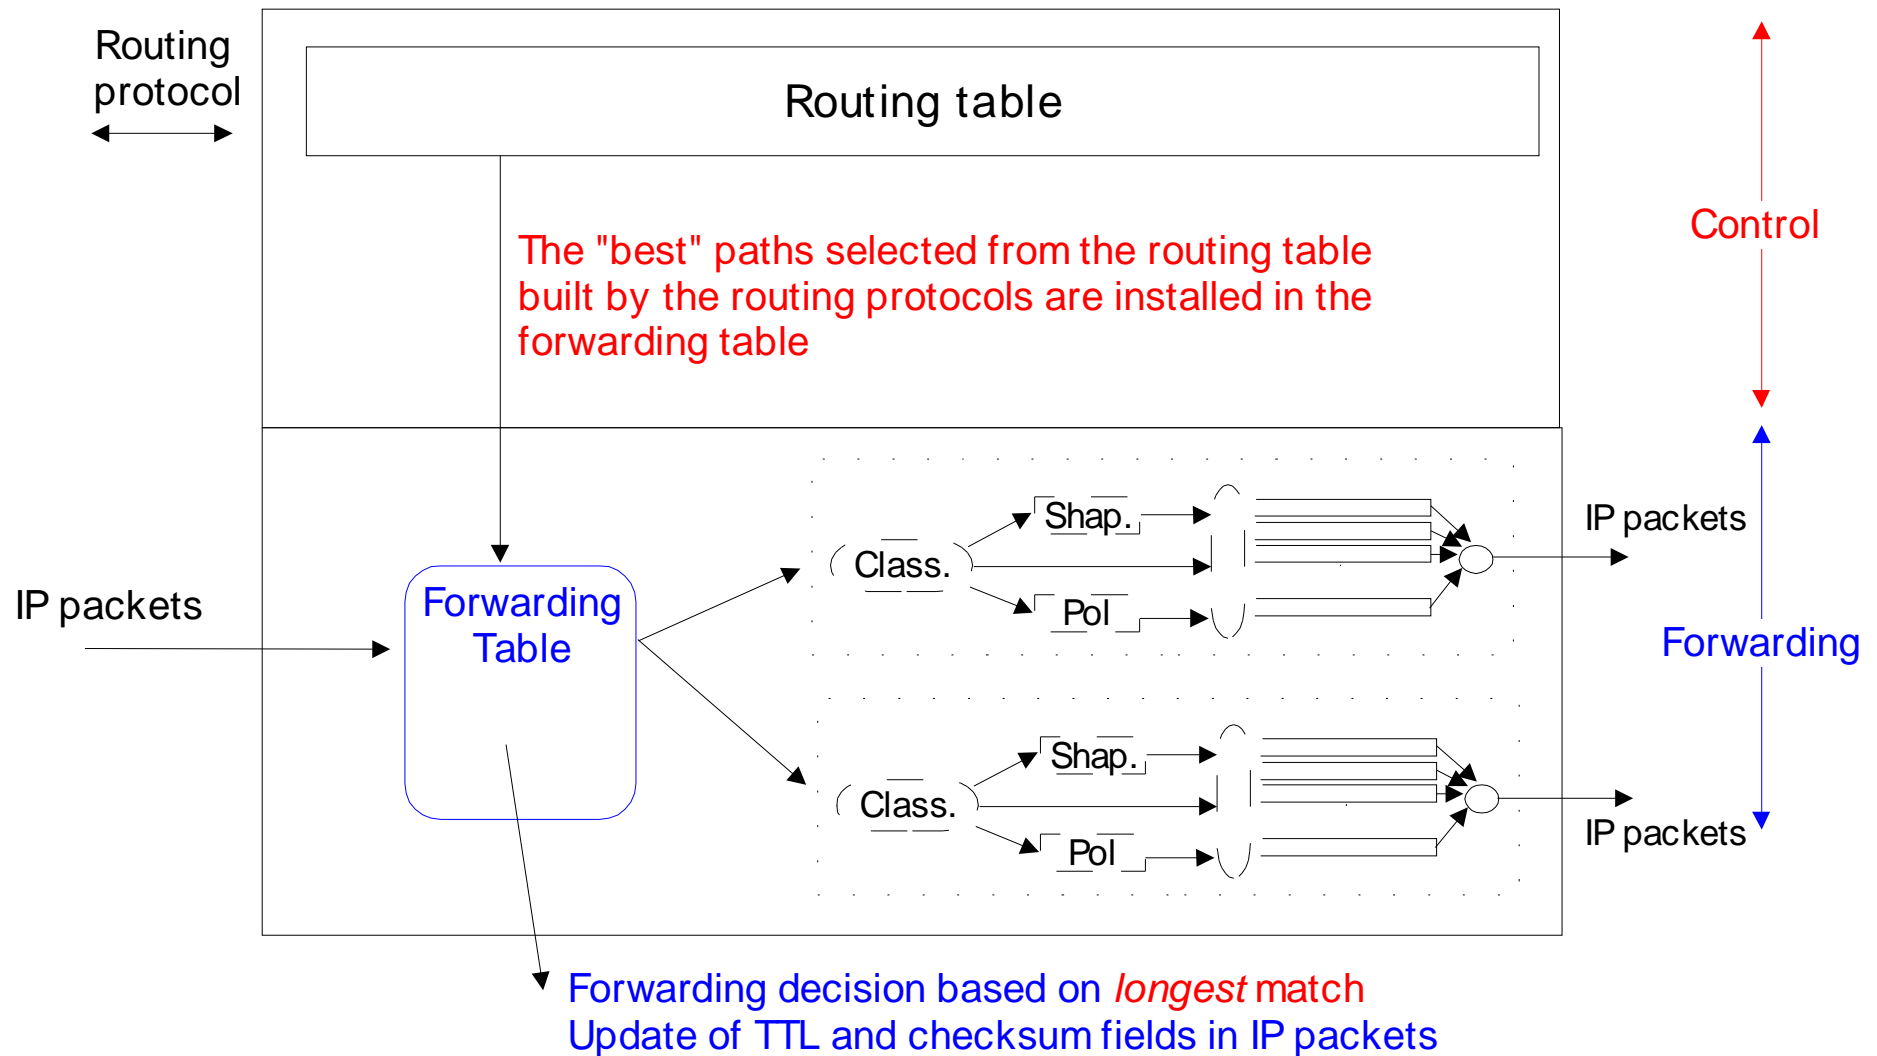

- BGP basics

- BGP in large networks

- Interdomain traffic engineering with BGP

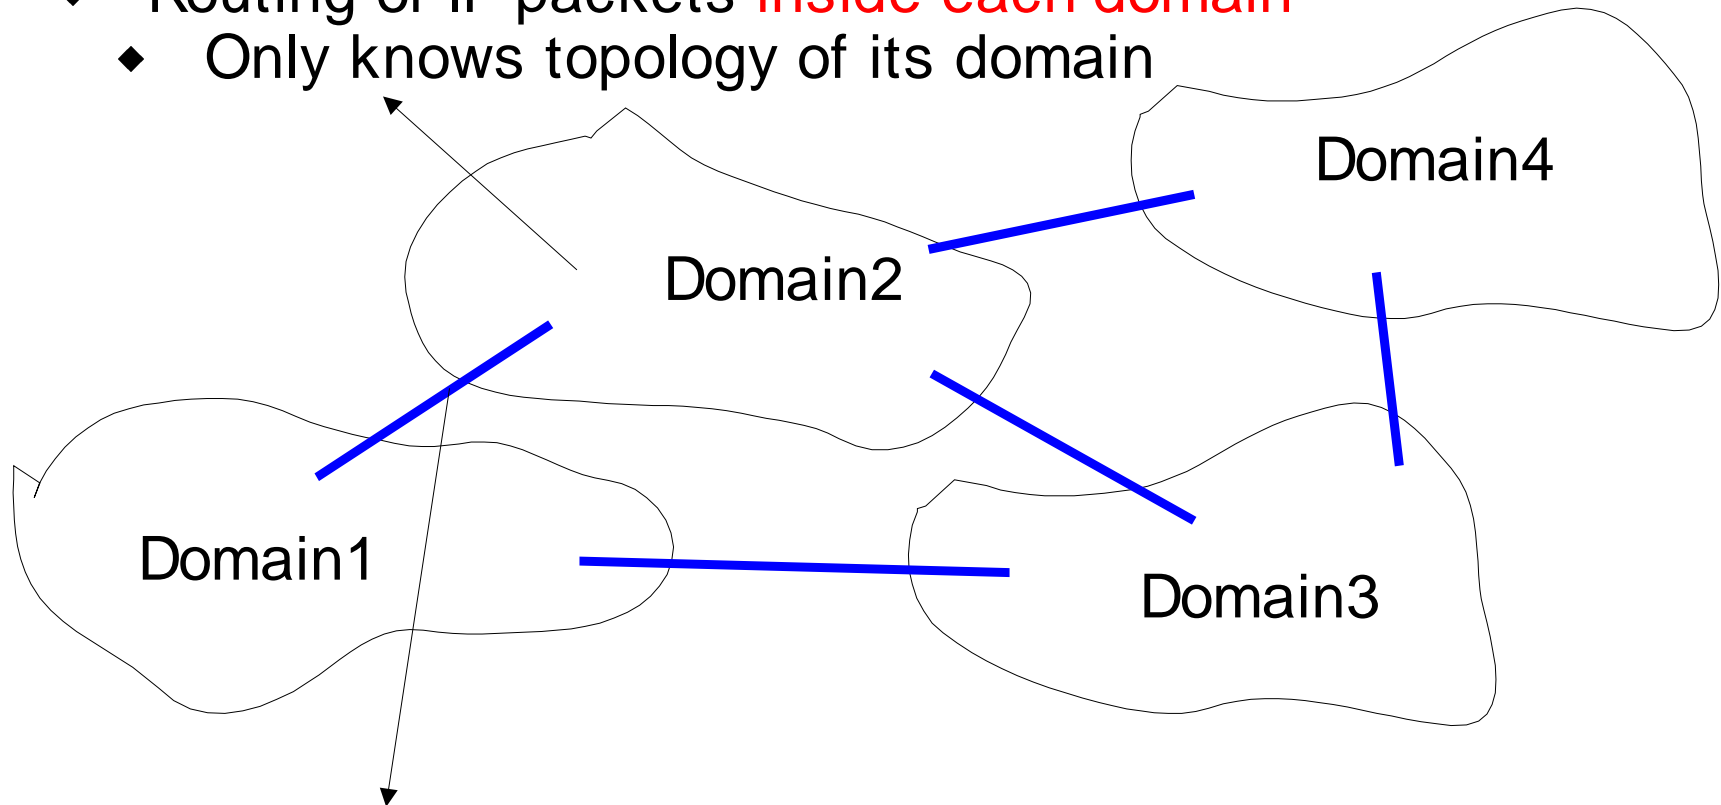

- BGP-based Virtual Private Networks

# Architecture of a normal IP router

# Internet routing

- **Interior Gateway Protocol (IGP)**
  - ◆ Routing of IP packets **inside each domain**
    - ◆ Only knows topology of its domain

- **Exterior Gateway Protocol (EGP)**
  - ◆ Routing of IP packets **between domains**
    - ◆ Each domain is considered as a blackbox

# Intradomain routing

---

- Goal
  - Allow routers to transmit IP packets along the best path towards their destination
    - ◆ **best** usually means the shortest path
      - ◆ Shortest measured in seconds or as number of hops
    - ◆ sometimes **best** means the less loaded path
  - Allow to find alternate routes in case of failures
- Behavior
  - All routers exchange routing information
    - ◆ Each domain router can obtain routing information for the whole domain
    - ◆ The network operator or the routing protocol selects the cost of each link

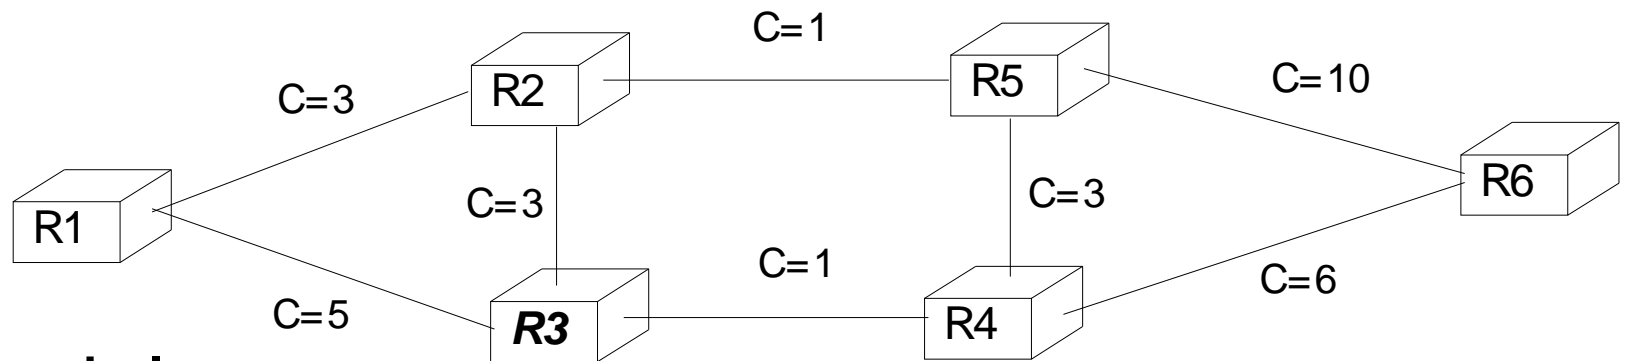

# Three types of Interior Gateway Protocols

---

- Static routing
  - Only useful in very small domains
- Distance vector routing
  - Routing Information Protocol (RIP)
    - ◆ Still widely used in small domains despite its limitations
- Link-state routing
  - Open Shortest Path First (OSPF)
    - ◆ Widely used in enterprise networks
  - Intermediate System- Intermediate-System (IS-IS)
    - ◆ Widely used by ISPs

# Distance vector routing

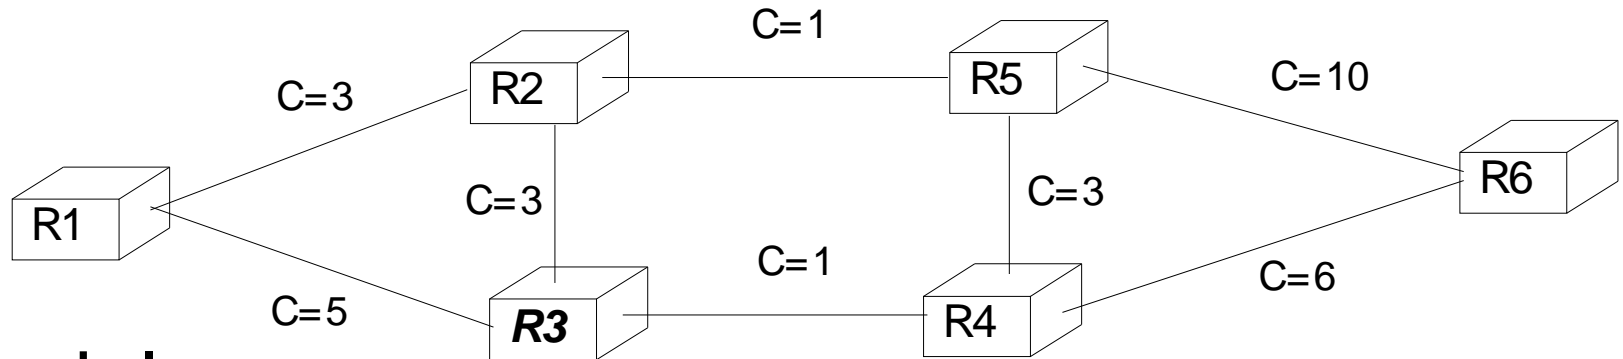

- Principle
  - Router configuration
    - ◆ Cost associated with each link
  - Each router sends periodically a distance vector containing, for each known prefix, :
    1. The IP prefix
    2. The distance between itself and the destination
      - The distance vector is a summary of the router's routing table
  - Each router receives its neighbor's distance vectors and builds its routing table based on those vectors

# Issues with distance vector routing

---

- How to deal with link failures ?
  - Routers should send their distance vector when they detect the failure of one of their links
- How to avoid the count-to-infinity problem ?
  - Utilize a non-redundant star shaped network
  - Limit the maximum distance between routers
    - ◆ For RIP,  $\infty=16$  !
  - Split horizon
    - ◆ Router A does not advertise to router B the routes for which it sends packets via router B
  - Split horizon with Poison reverse

# Link state routing

- **Principle**

- Each router builds link state packet containing its local topology
  - ◆ Link state packets are created at regular intervals and when the local topology changes
- Link state packet is reliably flooded to all routers inside the domain
- Each router knows the complete domain topology
- Computes routing tables by using Dijkstra
  - ◆ The best path is the path with the smallest cost

# IP forwarding

---

- Usually
  - Forwarding table contains, for each prefix
    - ◆ The prefix
    - ◆ The best path (outgoing interface) to reach this prefix
- Sometimes
  - Forwarding table contains, for each prefix
    - ◆ The prefix
    - ◆ **N** equal cost paths to reach this prefix
      - ◆ A first path (outgoing interface) to reach this prefix
      - ◆ A second path (outgoing interface) to reach this prefix
      - ◆ A third path (outgoing interface) to reach this prefix
      - ◆ ...
  - A load balancing mechanism is used to send the IP packets over the **N** available paths

# Load balancing algorithms

---

- Simple solution
  - Round-Robin or variants to dispatch packets on a per packet basis
- Advantages
  - ◆ easy to implement since number of paths is small
  - ◆ traffic will be divided over the equal cost paths on a per packet basis
    - ◆ each path will carry the same amount of traffic
- Drawbacks
  - ◆ two packets from the same TCP connection may be sent on different paths and thus be reordered
    - ◆ TCP performance can be affected by reordering

# Load balancing algorithms (2)

---

- How to perform load balancing without maintaining state for each TCP connection ?
  - Principle
    - ◆ concatenate IP src, IP dest, IP protocol, Src port, and Dest port from the IP packet inside a bit string
      - ◆ bitstring = [IP src:IP dest:IP protocol:Src port:Dest port]
    - ◆ compute path = Hash(bitstring) mod P
      - ◆ hash function should be easy to implement and should produce very different numbers for close bitstring values
      - ◆ candidate hash functions are CRC, checksum, ...
  - Advantages
    - ◆ all packets from TCP connection sent on same path
    - ◆ traffic to a server will be divided over the links
  - Drawback
    - ◆ does not work well if a few TCP connections carry a large fraction of the total traffic

# Summary

---

- Types of domains
  - Transit domain
  - Stub domain
- Intradomain routing
  - Selects the best route towards each destination based on one metric
    - ◆ Static routing
    - ◆ Distance vector routing
    - ◆ Link-state routing
  - Load balancing methods allow to place several paths in the forwarding table
